**OVERVIEW**

Abstract: Permafrost is permanently frozen soil in the near-surface. Impedance imaging techniques may enable monitoring of increased seasonal variation in land movement and slope stability brought by climate changes. We explore the constraints on an open-hardware embedded system for long-term remote monitoring of permafrost enabling preventative action prior to a catastrophic infrastructure failure.

Permafrost is a layer of permanently frozen soil (< 0°C for 2 years) which covers 24% of the landmass in the North to a depth of 1.5 km in some locations [1]. Changing climatic conditions have led to structural changes in permafrost: seasonal heaving of formerly stable land upon which civil infrastructure resides. A key indicator of these changes are the formation of “ice wedges” as well as sub-surface pooling of meltwater. Electrical Impedance Tomography (EIT), or equivalently Electrical Resistivity Tomography (ERT), is a promising technique for monitoring these localized changes in structure [2]. In warmer conditions, EIT systems tend to be designed for relatively low frequencies (1 Hz) and are often designed to be sensitive to humid soils and conductive ores. Frozen soils have much lower conductivities and temperature dependent permittivity, meaning current will propagate poorly unless stimulation frequencies in the 10’s or 100’s of kHz are used [3]. This means that the hardware design experience in the biomedical EIT community can be relevant to designing a multi-frequency system for permafrost EIT measurement. We explore the design constraints for an embedded system to be used in remote, long-term monitoring of seasonal changes in the resistivity of permafrost layers.

We have interviewed a number of hardware experts from the EIT community regarding their experiences designing EIT systems. We briefly summarize the design considerations identified during these interviews below.

**DESIGN CONSIDERATIONS IDENTIFIED**

An impedance imaging system can be broken down into a number of components as shown in Figure 1. Audio frequency analog circuits, low frequency A/D converters, and millivolt-range measurements imply a straightforward design. The components are relatively well understood but are deceptively challenging to implement well at 100kHz frequencies [4, 5]. In implementing these functional blocks, design choices and trade-offs must be made: frequencies of operation, noise tolerance, complexity, and reliability.

For products manufactured at a commercially viable scale or remote installations where on-site maintenance costs can be very high, reliability plays a key role. How much calibration, testability, and repeatability should be built into a system or be available in some adjacent system?

**ICE WEDGES**

Ice wedges form through repeated partial freeze-thaw cycles over many seasons, driving harder ice into cracked permafrost layers of mixed weaker material (Figure 2). Distinguishing types of ice may be possible by frequency-difference EIT (>10 kHz) or looking for anisotropic resistivity regions.

**DISCUSSION**

There are challenges in implementing an EIT system under new constraints. We aim to bring together the experiences of many in the EIT and ERT communities in designing these systems by working towards an open-hardware platform as a focal point for discussion of design constraints and trade-offs.

Acknowledgements: We would like to thank the following individuals for the time generously spent in describing their design choices, and their openness in sharing their implementation details: Ryan Halter (Dartmouth), Paul Wright (Manchester), David Holder & Kirill Aristovich et al. (UCL), Hervé Gagnon (Carleton), Peter Kramer (Swisscom), Jonathan Chambers & Paul Wilkinson et al. (British Geological Survey). We look forward to many more such discussions with those of you we have not had a chance to sit down with yet.
